Abstract—The Internet of Things (IoT) is expected to play an increasingly important role in next-generation mobile networks. Detailed knowledge of this type of traffic and the associated signaling in those networks is of interest to operators and standardization in order to run these networks successfully. The aim of this study is to characterize IoT signaling traffic for mobile communication networks (i) from a network operator’s point of view, (ii) at device level, and (iii) for the establishment of data connections. General statistics on signaling and device behavior, such as the observed IoT traffic volume and message composition, are given before device classes with statistically different signaling behavior are identified. Finally, by characterizing the aggregated signaling traffic, we show that the Markov assumption, widespread in standardization and literature, regarding the aggregated arrival process for data connections does not apply in reality.

Index Terms—IoT, mobile networks, signaling, dataset, modeling, measurement, GTP, SIGTRAN

I. INTRODUCTION

Assessing the traffic carried in a communication network is an important task in order to operate a network successfully. In particular with new types of traffic that have fundamentally different characteristics, such as the traffic occurring in the context of the Internet of Things (IoT) [1–5], those assessments are essential to plan and operate networks accordingly.

With IoT traffic, a number of new characteristics arise in the networks. By 2022, it is expected to have ~18 billion IoT devices, 1.5 billion of which use cellular connectivity [6, 7]. These devices span heterogeneous areas such as industrial, healthcare, residential, automotive, sports, and entertainment. Between 2016 and 2022 there is an average growth of 21% per year, driven by new use cases [7]. This growth in numbers as well as the heterogeneity raises the question of the scalability of the underlying infrastructure. Further, the characteristics of traffic are fundamentally changing with IoT, especially given the growth in machine-to-machine communications [8]. For 2020 about 41% or 12.86 billion IoT devices are installed as smart home devices [9]. The traffic generated by smart home IoT devices differs from the traffic generated by conventional devices [10]. In general, a mixture of machine-driven and event-driven traffic patterns is expected for upcoming IoT traffic [2].

From a technical perspective, this change in mobile traffic is met by a different handling of IoT devices in the networks

compared to previous mobile use cases. Newly emerging IoT mobile virtual network operators (MVNOs) run specialized service platforms providing worldwide device connectivity by leveraging already existing infrastructure of mobile network operators (MNOs) [11]. By providing global coverage to their customers through roaming agreements, MVNOs can provide their service without setting up a dedicated physical cellular network infrastructure. This is technically implemented with the IP exchange network (IPX) through which all physical and virtual providers that roam with each other are connected [11]. It is a separate network parallel to the Internet, so that mobile devices around the world can register with a physical, local mobile network, and their traffic is forwarded to the respective provider responsible for their SIM card, in case the provider has a roaming agreement with the given physical network.

This technical setup results in a mixture of traffic with unknown characteristics in the mobile core of MVNOs, since traffic comes from different locations and devices worldwide, different applications. In addition, different customers are being aggregated through the usage of the IPX network [11, 12]. This leads to unknown signaling traffic in the control plane, which results in significant uncertainties for the operation of networks [13, 14]. Overall, technical questions such as the volume of expected signaling traffic, the identification of certain classes of devices, or the identification of possible approaches to system optimization become important.

To provide a first step towards these issues, this paper aims at characterizing IoT signaling traffic for mobile networks (i) from a mobile network operator’s point of view, (ii) at device level, and (iii) for data connection establishment.

A large scale dataset is obtained by monitoring signaling transport (SIGTRAN) as well as 3GPP GPRS Tunneling Protocol (GTP) signaling traffic of over 270k IoT devices in cooperation with an MVNO that provides global IoT connectivity through over 500 roaming partners in 192 countries. In this work, we dissect the signaling behavior of devices using 2G/3G network connectivity and provide a broad overview regarding the signaling volume for both protocol stacks as well as a detailed evaluation regarding the occurrence of specific signaling patterns in the case of IoT traffic. Furthermore, we identify features characterizing the signaling behavior of single IoT devices and perform a device classification based on the identified signaling characteristics. We evaluate the signaling behavior exhibited by devices of different device classes and

show that the devices of different classes exhibit statistically significant differences regarding their signaling traffic. Finally, we dissect the arrival process of new data connections as a proxy for system load and present approaches to model the aggregated arrival process of the observed devices. We show that the Markov assumption, widespread in standardization and literature [2, 15–17], regarding the aggregated arrival process for data connections does not apply in reality. The methodology used to obtain the results as well as the structure of the document is shown in Figure 1.

The work is based on two major contributions. First, a large-scale dataset is presented containing signaling traffic of a global deployment of IoT devices from various use cases. Second, the dissection of signaling behavior and a subsequent proposal of classification metrics is given to distinguish IoT devices via their signaling traffic with an analysis of the corresponding arrival processes.

The remainder of this paper is structured as follows. Section II provides an overview of research work within the area of mobile IoT traffic. Section III introduces background information on MVNOs and their architecture including relevant signaling procedures. A general description of the dataset and preprocessing steps for preparing the raw data is provided in Section IV. Section V dissects the dataset and presents detailed general statistics. In Section VI, the classification mechanism and results are presented. Section VII deals with the analysis of the arrival process of new PDP context establishments. Finally, Section VIII concludes this work.

II. RELATED WORK

Previous related research in the field of IoT traffic falls into two categories. Investigation of traffic characteristics and datasets related to IoT deployments on the one hand and research regarding the signaling efforts of both machine to machine (M2M)-centric mobile networks as well as common mobile networks on the other hand. Studies investigating the traffic characteristics of IoT devices at a large scale, i.e. evaluating global scenarios including roaming devices, are still lacking from the general literature. Further, while all of the following studies investigate traffic patterns of IoT devices, they all focus on data plane traffic.

Regarding research on IoT traffic characteristics, the authors of [2] have compiled a taxonomy of available traffic patterns observed in IoT networks and investigated the applicability of the Poisson approximation in the context of IoT traffic. Further research in the area of IoT traffic modelling compares human generated traffic to M2M traffic [10, 18], proposed source traffic [5] and traffic models [15] as well as classification mechanisms for smart devices using WiFi [4] or general communication networks [1]. Finally, there exist studies analysing M2M communication [19]. However, all of the above focus on data plane traffic. Hence, when it comes to analyzing signaling traffic of mobile IoT devices beyond a single MNO, to the best of our knowledge, no other studies are available at the time of writing.

III. BACKGROUND

This section introduces the general architecture of an MVNO and provides a brief background on the signaling traffic that occurs when data roaming is carried out as in networks with MVNOs.

A. MVNO Platform Description

Figure 2 shows an abstract scenario of a device roaming in 2G/3G as it often happens these days in mobile networks. Here, the roamer connects to the locally available VPLMN¹ SGSN² and VLR³ for data connectivity with GTP⁴ and SIGTRAN⁵ connectivity with MAP⁶, respectively. This enables the device to log into the physically available visiting mobile network and a connection can be established. The visiting network components subsequently communicate with the corresponding services, HLR⁷ for SIGTRAN, GGSN⁸ for GTP, in the home network where the device is contractually registered. Signaling messages and data is sent via the visiting network to the core network of home mobile provider or MVNO of the device. The home provider pays the foreign network (VPLMN) that allows the roaming. The connection between the foreign VPLMN and the core network of the home provider is established by forwarding the signaling messages via the IP exchange network (IPX) from the device to the home core network. The IPX network is a telecommunications network for the exchange of IP based traffic between customers of separate mobile and fixed operators as well as other types of service provider (such as ISPs), via IP based Network-to-Network Interface. The forerunner of this network is the GRX (GPRS Roaming Exchange) network for routing the IP based commercial roaming traffic between visited and home operators. GPX and IPX are developed by the GSM Association. Further information on the roaming process and related signaling is detailed in [11, 12]. The colored marks in Figure 2 indicate the points of measurement at which signaling traffic has been monitored for the dataset used in this work since these are the only points for incoming signaling traffic for an MVNO. Note that the shown architecture is strongly simplified and only shows messaging flows relevant for the collected dataset, namely signaling between SGSN and GGSN, HLR as well as between VLR and HLR.

B. Roaming Signaling Procedures

During mobile roaming, devices need to perform two main procedures to establish either network connectivity or data connectivity: *network* and *data attachment*.

With only network connectivity, IoT devices can only send or receive calls or text messages. With data connectivity, the device can send IP data to the Internet or similar IP-based

services. Based on preliminary investigations, both modes have proven to be representative of IoT MVNOs, as some devices save energy and only perform network attachment, while others establish a full connection to the network with data connectivity.

For network attachment, devices perform an *attach procedure* to register with the visiting network VLR. The roamer sends an attach request to the VLR that includes, among other information, its identity (i.e. IMSI). Subsequently, the VLR initiates the *authentication procedure* with the corresponding home network HLR. After authentication, the VLR uses the *update location procedure* to update the location information stored at the HLR and thereby completes the procedure to establish network connectivity without data connectivity.

Analogously, signaling during data connectivity consists of similar procedures between the visited SGSN (VSGSN) and HLR. Instead of an *update location procedure*, the VSGSN initiates an *update GPRS location procedure*. Finally, the roamer can activate a new PDP context by requesting a home network APN (Access Point Name). The roamer’s request triggers the VSGSN to resolve the APN and a following *PDP Context Request* towards the home network GGSN (HGGSN). After successful completion, the roamer is able to use data connectivity.

IV. DATASET

A. Data Description and Processing

The raw data collected in this work consists of all SIGTRAN and GTP messages between HLR and VLR as well as between HLR and VSGSN in a roaming scenario. Consequently, all messages belong to the ETSI/3GPP Mobile Appli-

cation Part (MAP) protocol as part of the SS7 signaling system (ITU-T Q.700-series) or the 3GPP GPRS Tunneling Protocol (GTP) respectively. This includes signaling for *authentication* (SAI), *network attachment* (UL, UL_GPRS), *data connectivity* (PDP_CREATE, PDP_UPDATE, PDP_DELETE) as well as *mobility*.

These dialog types have been selected for further study as they, as well as their corresponding errors, contribute 95% of the total observed traffic volume. All remaining dialogs have been combined into groups labeled *OTHER* in the case of SIGTRAN and *PDP_OTHER* in the case of GTP. These dialogs are mostly related to SMS transmission and interrogation requests, which have not been evaluated in this work.

B. Dataset Overview

The dataset has been collected between 01.01.2020 and 31.01.2020. Figure 3 shows a timeseries over the whole month with the number of million dialogs per hour depicted along the y-axis. It can be seen that the timeseries exhibits gradual growth in signaling traffic over the monitored period. The blue line shows a linear regression with a constant of 0.71 million dialogs and a coefficient of 0.00042 million dialogs per hour. Furthermore, the data exhibits a cyclic pattern with 31 peaks, exactly the number of observed days. On January 8th an operator outage lead to a significant signaling incident, inducing roughly fourfold signaling traffic for about 20 minutes before returning to baseline. The specific reason for the incident in the visited network is unclear. In total, signaling traffic from 346 different mobile networks in 192 countries has been observed during the measurement period.

Table I presents an overview of key characteristics regarding the dataset. Between the two monitored signaling types GTP and SIGTRAN, roughly 274k devices have been observed, 84.1% of which have established at least one GTP tunnel in the observed time frame. In total, devices have generated around 1.4 billion signaling messages, 72.3% of which relate to successful signaling procedures. 14% are rejections by the system, which include disabled SIM cards as well as networks blocked by configuration. 11.9% are related to error responses for establishing PDP context, which includes technical errors as well as devices without remaining quota. After assembling the raw data into dialogs, about 650 million dialogs could be identified, 69.2% of which have been successful, 12.5% have

Fig. 3: Number of signaling dialogs over time in January 2020.

TABLE I: Dataset overview and key data points.

Protocol	Devices	Operators	Countries	Type	Messages		Dialogs	
					Abs.	Frac.	Abs.	Frac.

				Unknown	186	0.000	9	0.000

failed and 15.2% have been rejected by the system. A more detailed dissection of errors and rejected messages is provided in Section V-B.

V. GLOBAL IOT STATISTICS FOR THE DATASET

This section summarizes general IoT statistics for the dataset before presenting a detailed decomposition of the dataset. Finally, we present temporal correlations within the dataset and show common signaling patterns that have been observed.

A. General Statistics

On average, 172k unique IoT devices have been observed per day. A device is counted as active if either a successful updateLocation (UL) dialog after authentication or PDP context creation (PDP_CREATE) has occurred. Broken down to hours, roughly 55k devices are active on average. In total, all devices generate an average traffic volume of 20 million signaling dialogs per day, 875k per hour, or 244 dialogs per second within our dataset.

With regard to modeling purposes, the average number of signaling dialogs per day and device amounts to 103 with a standard deviation (sd) of 1485 and a coefficient of variation (c) of 14.4. The high coefficient of variation indicates high heterogeneity among devices.

Out of the 230k devices using data connectivity, on average, a device establishes 21.9 connections (sd: 84.7, c: 3.86) per day. The average duration is 2890 seconds (sd: 20205, c: 6.99). The high variation here is a further indicator for highly heterogeneous behavior of the devices active in the dataset.

B. Errors and Rejected Dialogs

Of the 1.4 billion signaling messages, 27.7% relate to unsuccessful signaling procedures, with errors and rejected messages contributing 12.5% and 15.2%, respectively. An

error is defined as an invalid sequence of signaling messages, such as incomplete or out of order interactions. As it is nearly impossible to identify the reason for incomplete dialogs, the observed errors are not evaluated in more detail at this point.

Some dialogs have been actively rejected by the home network. These contain mostly requests from devices equipped with SIM cards that have not been activated, are no longer active or are not allowed to establish data or phone connectivity. In this context, two reasons for rejected dialogs are prevalent.

Inactive SIMs. Of 650 million dialogs, roughly 13.4% are rejected due to devices with inactive SIM cards. These dialogs are generated by 8.3% of the devices (23 002 devices) that have at least one of their dialogs rejected with *UnknownSubscriber*. Hence, this relatively small number of devices is responsible for 13.4% of total signaling dialogs.

Invalid Roaming Attempts. Accordingly, 11 million dialogs (1.7%), generated by 15.2% of the devices (41 874 devices), are rejected due to invalid roaming partner selection. This occurs if a device selects a visited network that, e.g. due to policy reasons or customer configuration, cannot be used as a roaming partner. These dialogs fail with the message *RoamingNotAllowed*.

VI. DEVICE CLASSIFICATION

As already observed earlier, the signaling behavior differs significantly between devices. Hence, in the following section, we establish a set of device features extracted from purely evaluating signaling traffic and show that devices can be clustered using the k-means algorithm. In the feature set, the *error rate* as well as *reject rate* denote the fraction of dialogs resulting in errors or being rejected by the system, respectively. Further, the grade of *periodicity* of a device is defined as the sum of the autocorrelation values of the three most significant lags observed while calculating the autocorrelation for lags between 1 and 1500 in minutes. Thus, this evaluation is able

to identify periods of up to 24 hours for devices with up to three significant periods.⁹ Although further features have been evaluated, our investigations have shown that this minimal feature set is enough to classify devices observed in the trace. Note that Section VII introduces an additional feature to further refine the clustering performed here.

Evaluating the within-cluster sum of squares using the elbow-method, $k = 5$ has been decided to be a suitable number of clusters to perform the k-means algorithm on. The resulting clusters correlate with the expected outcome according to expert knowledge contributed by the MVNO. In order to visualize the results of the clustering, Figure 4 shows the biplot resulting from the primary component analysis and plotting the two most significant primary components against each other. Each point represents one device and the colors represent the assigned cluster. Additionally, the arrows and labels indicate the influence of the original features on the shown primary components. This visualization allows a visual identification of the relation between features and the resulting clusters. We identify the five clusters as *Non-Periodic* (Green), *Semi-Periodic* (Pink), *Periodic* (Blue), *High Error Rate* (Red) and *High Reject Rate* (Yellow).

Fig. 4: Biplot of two most significant primary components and influencing original features.

Figure 5 shows the distribution of devices among those five identified clusters. It can be seen that a significant portion of devices exhibits non-periodic or semi-periodic behavior, with the other classes containing only 16% of devices altogether.

VII. AGGREGATED PDP CONTEXT ARRIVAL PROCESS

Finally, in order to better understand the underlying arrival process of the devices resulting from the performed classification, we examine the aggregated arrival process of newly established data connections. To this end, we dissect the arrival process of PDP_CREATE dialogs. This subset of messages

⁹Devices with single period p also exhibit high autocorrelation values at $2p$ and $3p$.

has been selected as it acts as a proxy for the general system load for MVNOs since a successful PDP_CREATE requires successful SAI, UL, and UL_GPRS dialogs beforehand.

As already stated before, large parts of literature and standardization [2, 15–17] assume Markov properties when dealing with the aggregated arrivals in large scale IoT environments. The Markov assumption is suitable as the superimposed traffic of an infinite number of sources exhibits memorylessness, according to Palm-Khintchine [20]. However, in the following, we show that the assumption does not hold true in reality due to the presence of time synchronous devices, but can be restored through additional device classification and filtering. Similar observations have been made in the past, e.g. [4]. Note that the synchronous behavior of devices is expected to stem from firmware implementation specifics rather than actual synchronization between independent devices. Devices seem to be programmed to transmit data at fixed times, instead of fixed intervals, resulting in pseudo synchronous behavior in the aggregated traffic.

To this end, Figure 6 shows the message density over one hour for all device classes for the whole trace. Hence, the y-axis shows the probability of an arbitrarily selected dialog happening within the corresponding minute along the x-axis. The plot is shown to visualize the synchronized behavior of devices within the trace. Although devices are expected to not synchronize their signaling behavior with other devices, clear synchronization patterns can be observed within the trace. Specifically, increased density between 0 and 5 minutes as well as peaks at minutes 0, 5, 15, 35 and 45 can be observed. This behavior violates the assumption of memorylessness, as in a process exhibiting the Markov property, the message density would need to be constant.

However, based on the message density function of single devices, we are able to identify time synchronous devices and hence divide the arrival process in synchronized and non-synchronized devices. To this end, we examine the maximum message density for messages of a specific device, as is shown in Figure 6 for all devices. This classification is based on the assumption that the message density function of a non-periodic, non-synchronized device would follow a uniform distribution. Figure 7 shows the ECDF of the maximum message density over all devices with at least 30 activity phases. This limitation is introduced as the density value is not significant for devices with less than one activity per day.

Based on the distinct knee observed in the figure, devices with a maximum message density of at least 0.075 are classified as synchronized. This results in 23% of devices being classified as synchronized. Note that this classification has been performed in addition to the clustering performed earlier, so each device can be classified by both their signaling behavior as well as their synchronicity. Figure 8 shows the same plot as Figure 6 with devices split into synchronized and non-synchronized classes.

It can be seen that non-synchronized devices now exhibit a uniform message density distribution while synchronized devices feature the peaks observed before as well as low baseline density.

Fig. 5: Devices classified by signaling behavior via k-means.

Fig. 6: Message probability density function of PDP_CREATE dialogs for the probability that messages occur at a specific minute within any hour during the entire trace.

Fig. 8: Message probability density of PDP_CREATE dialogs over minutes within any hour of the trace per synchronization class.

Fig. 7: ECDF of maximum message density over all devices with at least 30 activity phases.

Fig. 9: Q-Q-plot of interarrival times of non-synchronized devices.

Base on these observations we can now assume the arrival process of non-synchronous devices to exhibit memorylessness and consequently negative exponentially distributed interarrival times. To this end, Figure 9 shows the Q-Q-plot of the empirical interarrival times of all non-synchronized devices, irrespective of device class, and the corresponding negative exponential fit. The red marks show the 10% to 90% quantiles, the gray marks show the 1% to 99% quantiles. It can be seen that the interarrival times of the aggregated process of all non-synchronized devices can be closely approximated using an exponential distribution as it is the case for Markov processes. Furthermore, the interarrival times exhibit no significant autocorrelation with the largest observed value being 0.017 for lags between 1 and 1000.

VIII. CONCLUSION

In this work, we presented the results of our analysis of a 31 day IoT signaling trace containing more than active 270k IoT devices of an MVNO operating worldwide. We found that about 84% of the observed 2G/3G devices use data connectivity with the remaining 16% only using network connectivity for phone and text messaging as they do with circuit-switched services. We have shown that devices exhibit significant differences regarding their signaling behavior and

extracted features that allow the modelling of different device classes based on the rate of erroneous and rejected dialogs as well as the periodicity of devices. We have shown that devices identified by this classification mechanism exhibit statistically significant differences when it comes to their signaling behaviour. Finally, by evaluating the aggregated arrival process of new data connections, we have shown that the often assumed memorylessness does, surprisingly, not hold true in reality due to the presence of time synchronous devices, but can be restored through additional classification and filtering steps. Next steps include the behavioral classification of different IoT devices to better understand their behavior and be able to move towards a detailed source traffic model of single devices as well as performance models of large scale systems.

ACKNOWLEDGMENT

This work is funded by the Bavarian Ministry of Economics, Regional Development and Energy within the project *SCALE* as part of the R&D program for information and communication technology in the field of 5G mobile communications. The authors alone are responsible for the content.
